Credit Conditions when Lenders are Commonly Owned

Mattia Colombo, Laura Grigolon and Emanuele Tarantino*

March 7, 2021

Abstract

We investigate how common ownership between lenders affects the terms of syndicated loans. We provide a novel view on common ownership as a mechanism to mitigate the effects of information asymmetry on borrowers' quality. As the lead bank does not need to signal the quality of the borrower by means of dissipative signals, high common ownership should have a negative impact on loan rates, the share of the loan retained by the lead bank, and the dispersion in loan returns. We empirically verify all three predictions, leveraging on differences in the level of common ownership across lenders and facilities within a loan. Common ownership affects the terms of the loan more strongly in presence of opaque or new borrowers, when the lead arranger is more likely to hold an information advantage over the syndicate members. As information flows from the lead arranger to syndicate members, we show that member-to-lead and member-to-member common ownership does not affect the terms of syndicated loans.

1 Introduction

Over the last two decades, the banking sector has become increasingly interconnected because of the steady growth of shareholders owning equity in multiple banks: the literature refers to those shareholders as common owners. The four largest asset managers (Blackrock, Vanguard, State Street and Fidelity) hold a combined 20% of the shares of the four largest U.S. commercial banks (JP Morgan, Citigroup, Bank of America, and Wells Fargo). At the same time, these four banks issued around two thirds of all commercial loans between 1990 and 2013.

Asymmetric information is another defining feature of banking markets, with consequences in terms of risk pricing and credit rationing. Borrowers employ a variety of strategies to signal attractive attributes to the uninformed lenders by introducing distortions in contracting: Spence (1974) and Leland and Pyle (1977) are two early seminal contributions. In the syndicated lending industry, the lead bank, who conducts the due diligence and acts on behalf of the borrower, may mitigate asymmetric information vis á vis the syndicate members by detaining a larger share of the loan (Sufi, 2007; Ivashina, 2009). In banking, direct sharing of borrower information is an effective tool to ease information asymmetries (Padilla and Pagano, 2000; Jappelli and Pagano, 2002). In this paper, we show that common ownership allows lenders to achieve the same result.

We investigate how common ownership between lenders affects credit conditions. A recent body of empirical work provides evidence in support of the common ownership hypothesis: the hypothesis suggests that, as firms in the same industry are held by one overlapping investor, those firms may internalize the interests of their competitors via the financial stakes held by the common shareholder. Schmalz (2018) and Backus et al. (2019) provide comprehensive reviews on this growing literature. Using data on syndicated loans, we put forward and test a novel mechanism through which the presence of overlapping ownership affects the actions of interconnected firms. We conjecture that a lender with superior information on a borrower risk profile, like the lead bank in syndicated loans, credibly transmits such information to another lender when the two are closely interconnected via a common shareholder. We then study the impact of common ownership on lending conditions. To perform our tests, we empirically leverage on differences in levels of common ownership across lenders (lead bank and syndicate members) that extend syndicated loans to corporations.

First, we empirically document a positive relation between common ownership and directors shared between lenders. This positive association supports the idea that information transmission is plausible, for example through common directors, when common ownership between lead and members of the syndicate is sufficiently high. Second, we propose a stylized model with asymmetric information to derive empirical predictions

regarding how common ownership narrows the information gap between the lead bank and the members of a syndicate. The lead bank represents a penniless borrower. The borrower privately observes the type of its project, which can be either good or bad, and this information is shared with the lead bank.[1] As the assets of the lead bank are not sufficient to fund the venture, the lead bank needs to form a syndicate to cover the investment. We distinguish between two scenarios: high and low common ownership. Information on the borrower type can be credibly transmitted by the lead bank to the syndicate members only in presence of high common ownership. We find that, if common ownership is high, the lead bank and the commonly owned members of the syndicate share the information regarding the firm's project type, and lending takes place at the conditions that would prevail with symmetric information. With low common ownership, asymmetric information implies that, to signal the good type, the lead bank will have to promise higher returns to the syndicate members and commit its funds in the loan. An ancillary consequence of lower returns with common ownership is that lending conditions should exhibit higher variability.

The syndicated lending market provides an ideal setting to test this theory. A syndicated loan typically consists of a number of tranches (facilities), with essentially the same default risk and creditor rights. After receiving the mandate, the lead bank announces to the market the non-price characteristics of the loan (like collateral and maturity). The price of each facility, and the composition of the syndicate, is set on the market. Lenders can force the borrower into bankruptcy if credit events occur, such as payment defaults or covenant violations. These features imply that the risk of the underlying asset is held constant within a loan; thus, we can credibly identify differences in lending conditions between facilities *within* a loan with varying degrees of common ownership.

We find support for our three predictions in the data. First, high levels of common ownership between the lead bank and the syndicate participants are associated with lower prices. We estimate the impact of common ownership on prices using variation in common ownership across facilities and loans. We obtain these results in specifications that account for other factors affecting the loan spread, including an extensive set of controls related to (i) the loan and the facility; (ii) the borrower; (iii) the lender. We employ multiple fixed effects to difference out alternative interpretations such as confounding effects of demand and supply variations. We account for variation in facility type and loan purpose; industry-year-quarter fixed effects control for aggregate variation in demand for syndicated loans in each sector. Borrower fixed effects account for unobserved time-invariant heterogeneity across borrowers, and lead bank fixed effects capture time-

[1]The source of asymmetric information can be the probability of successful project completion, as we currently assume in the model, or the cost of monitoring the firm (as in Sufi (2007)). The qualitative nature of the results remains unchanged.

invariant supply factors. Coefficient estimates indicate that an increase of one standard deviation in common ownership is associated with a lower spread of 5.34 basis points.

To rule out the possibility that variation in common ownership and spread may reflect omitted characteristics that systematically correlate with prices and common ownership levels, we estimate the effect of common ownership on the pricing of facilities of the same type within the same loan. The within-loan estimates confirm the negative effect on prices: an increase of one standard deviation in common ownership implies a reduction in spread of 9.18 basis points.

Finally, we discretize our common ownership measure into five indicator variables corresponding to the quintiles of its support. All our estimates show that reductions in spread are relevant only for high levels of common ownership (quintile 4 and 5), and those reductions are monotonically increasing in common ownership. Within a quintile, a change in common ownership in a facility from the minimum to the maximum level reduces the price by roughly 10 to 20 basis points, where the average loan spread is around 197 points for the upper quintiles. These effects are heterogeneous across borrowers: common ownership has a stronger impact on loan prices in presence of opaque or new borrowers, when the lead arranger carrying out the due diligence is more likely to hold an information advantage over the uninformed syndicate participants.

Second, we find that an increase of one standard deviation in common ownership is associated to a statistically significant 0.64 percentage point decrease in the amount of loan retained by the lead bank. As before, the effect is non-linear: the lead banks of syndicates in the top quintiles of common ownership (quintiles 3 to 5) retain a significantly smaller share of the facility with respect to the bottom quintiles. Within a quintile, an increase in common ownership from the minimum to the maximum level implies a reduction in the amount of facility retained by the lead corresponding to roughly 1.7 percentage points in quintile 3 and 2.7 percentage points in quintile 4 and 5. As the lead arrangers retain on average 21% of the facility amount, the impact of common ownership is sizeable.

Third, high common ownership should imply lower price dispersion. We verify that an increase of one standard deviation in common ownership is associated with a 2.97 basis points decrease in the standard deviation of the loan rates.

We are careful to rule out alternative explanations to our findings. First, we explicitly control for vertical relations, namely common ownership between lenders and borrowers. Second, we run two falsification tests of our hypothesis: as only the lead bank possesses superior information on the riskiness of the borrower, the level of common ownership from the syndicate member to the lead arranger or between members should not affect the credit conditions. We find that member-lead and member-member common ownership has no impact on any of the outcome variables, which constitutes an indirect confirmation

that information transmission is effectively initiated by the lead bank.

Finally, we worry about the fact that common ownership is the result of the syndicate structure. As the lenders decision to enter the syndicate is not random and may depend, among other factors, on the level of common ownership with the lead arranger and other unobservables collected in the error term, we extend our model to account for this form of self-selection. Our results do not qualitatively differ when accounting for selection. We also conjecture that the decision of potential lenders to enter the syndicate and fund the loan essentially depends on the credit risk of the borrower. In contrast, the choice of the specific facility should mainly depend on lender-specific preferences. As a consequence, the composition of the syndicate across facilities within a loan should not depend on the degree of common ownership. We empirically confirm that common ownership is not a driver of participation in the single facilities of a loan.

Regulators explicitly acknowledge that common ownership between the lead bank and potential syndicate members can be conducive to the transmission of information regarding the borrower (The European Commission, 2019). This practice is not regarded as anticompetitive per se as long as it does not harm the borrower, for example by artificially raising prices. Our results give practical guidance to policy makers. We provide empirical evidence consistent with the presence of a flow of information between the lead bank and the commonly owned syndicate member banks. As a result, the effects of information asymmetries on contractual terms are mitigated through common ownership.

Related literature Our paper proposes a new mechanism through which common ownership between lenders affects lending conditions. Specifically, we show that common ownership reduces the distortions in credit conditions that arise with asymmetric information. We contribute to several strands of the literature.

The literature on syndicated lending has well documented how asymmetric information affects lending conditions, and in particular the lead bank's loan retention strategy to mitigate the costs of asymmetric information (Sufi, 2007; Ivashina, 2009).[2] Other aspects of syndicated lending examined in the literature include how the composition of the syndicate affects loan spreads (Lim et al., 2014), the propensity to syndicate a loan (Dennis et al., 2000), the relationship between final spreads and fees (Berg et al., 2016; Cai et al., 2018), the role of covenants (Drucker and Puri, 2009). We exploit the institutional features of the syndicated lending market (and, in particular, the heterogeneity of syndicate composition across facilities of the same loan) to identify the impact of common ownership between lenders on lending conditions. Our results suggest that common ownership alleviates the costs of asymmetric information.

[2]Bruche et al. (2020) provide an alternative explanation for the retention strategy, which hinges on the presence of pipeline risk on the side of the lead bank.

Lately, common ownership has attracted significant attention by financial and industrial economists. The literature mainly focuses on the common ownership hypothesis, according to which an investor holding a controlling stake in several firms belonging to the same industry might, in turn, influence their pricing with the purpose of softening competition (Azar et al., 2016, 2018; He and Huang, 2017).[3] More relevant to us are Cici et al. (2015), Ojeda (2019) and Wang and Wang (2019): they study the impact of common ownership between lenders and borrowers. Overall, they document lower loan spreads, larger loans and more frequent lending activity in the presence of common ownership. Differently from these papers, we look at common ownership between lenders. We find empirical evidence consistent with the results of a model in which, thanks to common ownership, the lead bank does not need to signal the quality of the borrower by means of "dissipative" signals (Tirole, 2006), such as retention of a share of the loan. In all our specifications, we nevertheless account for relations of common ownership between lenders and borrowers, which excludes the possibility that our results are driven by borrower-lender overlapping ownership.

2 Institutional Setting

2.1 The Syndicated Loan Market

Syndicated lending is an important source of financing for U.S. corporations. Sufi (2007) and Ivashina (2009) report that more than 90% of the largest 500 non-financial Compustat firms in 2002 obtained a syndicated loan between 1994 and 2002. In 2006, syndicated loan issuance surpassed corporate bond issuance with a volume of $1.7 trillion. More recently, the Federal Reserve's Terms of Business Lending survey documented that 44% of all commercial loans in 2013 were made under syndication.

The syndicated loan market operates over the counter. Transactions are the result of informal interactions between borrowers and lenders. The borrowers are firms that seek funding from the syndicate to leverage large capital investments. The syndicate is headed by the lead bank, or arranger. The other syndicate members are banks or institutional investors.

The borrower solicits potential lead banks to submit a bid. These banks propose their

[3]Boller and Morton (2020) use inclusion in a stock market index to identify the impact of an increase in the overlap among investors. Newham et al. (2018), Ruiz-Pérez (2019) and Gerakos and Xie (2019) analyze the effect of common ownership on entry. Antón et al. (2021) investigate how managerial incentives can link common ownership and competition. Aslan (2019) looks at the relation between common ownership and costs. Backus et al. (2021a) use a conduct test to reject that common ownership has large effects on markups. Comprehensive reviews of this growing literature by Schmalz (2018) and Backus et al. (2019) provide a summary of the empirical evidence.

syndication and pricing strategy to the borrower. The chosen lead bank then receives the mandate to issue a loan and performs the due diligence. Details of the mandate signed between the lead bank and the borrower remain confidential, including any potential rearrangement of the fees to the lead bank depending on the outcome of the syndication.

The loan issued by the lead bank is divided into tranches, or facilities, of different types (credit line, term loan), amount and maturities. All non-price terms of the loan, such as type, amount, maturity, purpose, collateral, and covenants, are set before the marketing phase starts. Only type, amount, and maturity vary across facilities within a loan. Finally, the interest rate paid to syndicate members, calculated as the spread over LIBOR, and the composition of the syndicate are determined during the marketing phase. Specifically, the lead bank proposes the price for each facility in the loan, and potential syndicate members decide whether they wish to buy at the specified spread. The deal is closed when the desired level of demand is met. The lead bank can subscribe part of the loan to close the deal, although it does not have an obligation to do so. Finally, if a credit event occurs, like a missed repayment or a covenant violation, syndicate members can force the borrower into bankruptcy.

2.2 Connections between lenders and common ownership

Mutual funds, such as Black Rock, Vanguard, State Street and Fidelity, are often shareholders in both the lead bank and the syndicate members, and their holdings have been growing over time, as documented in Table A1. The literature (Appel et al., 2016; Brav et al., 2019) presents evidence that these mutual funds use their voting blocs to influence target firms' governance. In practice, mutual funds may exert their control through "voice" (Edmans et al., 2019), by direct interventions such as monitoring of the management or by suggesting strategic changes. Matvos and Ostrovsky (2008) show that, in mergers with negative acquirer announcement returns, mutual funds holding shares in both the acquirer and the target are more likely to vote for the merger. He et al. (2019) provide evidence that institutional investors play a more active monitoring role when common ownership is high. Appel et al. (2016) show that the presence of mutual funds has a direct impact on the composition of the board of directors, and in particular an increase in ownership by passive funds is associated with an increase in non-executive directors entrusted by the shareholders.

In our empirical framework, we study situations in which the lead bank and the members in the syndicate are commonly owned by mutual funds, with variation in the level of common ownership across loans and across facilities within a loan. Our conjecture is that common ownership may facilitate the transmission of private information regarding the borrowing firms from the informed lead bank to the uninformed members of the

syndicate. In line with the literature cited above, we expect that information channeling is more likely when the common owner holds larger voting blocs. Regulators explicitly recognize the possibility of such influence: in a recent report on loan syndication and competition in credit markets, the European Commission acknowledges that information transmission may arise when the lead bank and syndicate members are commonly owned (The European Commission, 2019).

As shared directors can serve as a simple information transmission mechanism across lenders, we investigate the association between common ownership and directorship interlocks in our setting. For each pair of lead bank-potential syndicate member, we define a director interlock as an indicator equal to one if (i) at least one director sits on the boards of both banks; or (ii) at least one director from each pair serves on the board of a common third firm. Information on directors and their joint employments is retrieved from BoardEx, with yearly frequency, for the period 1999-2013.[4] We then describe the probability of director interlocks by regressing the indicator on a measure of common ownership and an extensive set of covariates capturing characteristics of the lender pair.

In Table I, we empirically document within our setting a positive relation between common ownership and shared directors. The table presents the results of a linear probability model: pairs of lead bank-potential syndicate member with higher levels of common ownership are more likely to exhibit interlocking directorships. This positive association remains significant after controlling for: (i) characteristics of the lenders: their size, equity, book leverage, return on assets, and whether they belong to S&P 500; (ii) characteristics of the lender pairs: their portfolio similarity and their past relationships; (iii) year dummies. These results support the hypothesis that, in our setting, common ownership can constitute a communication device between firms if it is sufficiently large, as common directors are more likely at higher levels of common ownership. Our findings complement the work of Azar (2012), showing descriptive evidence that firms with common owners are more likely to share directors, and Nili (2020), documenting the rise of so-called horizontal directors, serving on the boards of multiple companies within the same industry.

3 The Model

Consider a penniless firm that owns a project but lacks financial resources to carry it out. The firm delegates the lead bank (L) to form a syndicate for a loan of size 1; it then shares with the lead bank the returns of the investment. A continuum of potential members of the syndicate (M) operate in perfectly competitive financial markets and

[4]Our common ownership measure is built at quarter-year level. Because of the information on directors is at yearly frequency, we use the measure of common ownership from the last quarter of each year.

have the financial resources to fund the project. We denote by A, with $0 < A < 1$, the maximum amount of the loan that the lead bank can pledge. A then represents the lead bank's "inside liquidity".

The firm's project can be one of two types. The good type (G) has a probability of success equal to p. The bad type (B) has a probability of success $q < p$. In either case, the project yields R in the case of success and 0 in the case of failure. Throughout the scenarios we consider, the lead bank always knows the type of the firm's project. We impose the following parametric conditions.

Assumption 1.

$$pR > 1 > 1 - A > qR, \quad qR - A > \frac{q}{p}.$$

$pR > 1$ implies that the good firm's project has a positive net present value (NPV). $1 - A > qR$ means that the bad firm's project has a negative NPV despite the use of the lead bank's funds A. Finally, $qR - A$ is the project return of a lead bank representing a bad type (qR), net of the "inside liquidity" A. $qR - A > q/p$ implies that the value of such net utility is large, which, as we will see, makes signaling the good type particularly costly for the lead bank. The likelihood that this condition is met decreases with the degree of adverse selection. As q falls, keeping all the rest fixed, it is more difficult to meet the inequality.

The contract we consider is $(x_j, R^s_{j,L}, R^f_{j,L}, R^s_{j,M}, R^f_{j,M}, \mathcal{A}_j)$, with $j \in \{G, B\}$. We denote by $x_j \in \{0, 1\}$ the decision on whether a lead bank representing a firm of type j receives funding by the potential syndicate members. The share of the returns on a project of type $j = G, B$ received by $i = L, M$ in the case of success (s) is $R^s_{j,i}$, it is $R^f_{j,i}$ in the case of failure (f). We assume for simplicity that $R^f_{j,L} = 0$; $R^f_{j,M} = 0$ is an implication of limited liability. Finally, $\mathcal{A}_j \leq A$ is the amount of cash invested by L in the loan. Suppressing the notation for success, the contract can be rewritten as $(x_j, R_{j,L}, R_{j,M}, \mathcal{A}_j)$, with $j \in \{G, B\}$.[5]

We parameterize by $\kappa \in [0, 1]$ the level of common ownership between the lead bank and the syndicate member, where κ is the weight that the lead bank L places on the profits of the commonly owned syndicate members M. A value of κ equal to zero corresponds to a situation of separate ownership, and a value of κ equal one means that the lead bank assigns the same weight to its own profits and the ones of the potential syndicate member.[6] We solve the model under two scenarios. In the first, we consider a funding

[5] $R_{j,L}$ is then split between the lead bank and the firm according to a bargaining game that is outside the model.

[6] Similarly to Antón et al. (2021), we restrict κ within values in the unit interval. Values of κ larger than one are empirically possible: they correspond to situations in which the lead bank places more weight

game without common ownership ($\kappa = 0$). In the second, we consider a funding game with high common ownership (corresponding to a situation in which κ is larger than some threshold $\underline{\kappa} > 0$). In our model, high common ownership allows the lead bank and the syndicate members to channel L's private information regarding the borrower's probability of success, provided it is optimal to do so. This approach is motivated by the evidence in Section 2.2, documenting that commonly owned banks share a network of directors that facilitates the transmission of information. Whether information sharing takes place, however, will be an equilibrium decision.

We use α and $(1 - \alpha)$ to denote the potential syndicate members' prior probabilities that the borrower's project is of type G and type B, respectively, with[7]

Assumption 2.

$$[\alpha p + q(1 - \alpha)]R \geq 1.$$

Assumption 2 implies that there are enough good-type projects in the pool of firms to compensate for the negative NPV of bad-type projects.[8]

In the negotiations with M, L holds all the bargaining power. When indifferent, L will prefer not to commit any cash in the loan (i.e., $\mathcal{A} = 0$). This reflects, e.g., the presence of alternative investment opportunities that are more remunerative than the firm's project. Finally, all agents are risk neutral, the lead bank is protected by limited liability, and the risk-free interest rate is nil.

We use the model to derive empirical predictions on the two main features of syndicated lending contracts in the data, with and without common ownership: the interest rate paid to the syndicate members and the amount of the loan retained by the lead bank. We use $\mathcal{A}_G$ to denote the amount that the lead bank pledges in the loan, and $1 + r = R - R_{j,L}$ for the interest rate to syndicate members. By this formula, we capture the all-in-drawn spread paid by borrowers, which is what we observe.

3.1 Equilibrium analysis

Funding without common ownership If common ownership is sufficiently low ($\kappa < \underline{\kappa}$), or absent ($\kappa = 0$), information sharing cannot happen; thus, L negotiates with M

on the profits of the commonly owned syndicate members than on its own profits. As a consequence, the lead bank would have the incentive to transfer its funds to the syndicate members.

[7] In this model, α can also be interpreted as the fraction of good-type firms in the economy, or the probability that a given firm is of type G.

[8] Absent this condition, the only equilibrium with asymmetric information would feature market breakdown.

under asymmetric information.[9] For the sake of the exposition, we consider the case in which $\kappa = 0$. In the application, we will empirically identify the threshold $\underline{\kappa}$.

With symmetric information, the lead bank rejects the loan to the bad type ($x_B = 0$) and grants the loan to a good type ($x_G = 1$). Moreover, it does not pledge its funds in the loan to the good type ($\mathcal{A}_G = 0$), and sets the return to investors so to satisfy their break-even condition ($R_{G,M} = 1/p$ and $R_{G,L} = R - 1/p$). If these contracts were available, a lead bank representing a bad firm would mimic the good firm. That is, it would pretend to be of the good type, its utility would be positive (because $pR - 1 > 0$), but the syndicate members would not break even upon accepting. The question, then, is whether there exists a separating contract that is unappealing to a bad borrower and allows the potential members to break even.

Proposition 1. *Without common ownership, the separating contracts offered by the lead bank are* $(x_B, R_{B,L}, R_{B,M}, \mathcal{A}_B) = (0, 0, 0, 0)$ *and*

$$(x_G, R_{G,L}, R_{G,M}, \mathcal{A}_G) = (1, A/q, R - A/q, A),$$

and all potential syndicate members accept.

Proof. We set $(x_B, R_{B,L}, R_{B,M}, \mathcal{A}_B) = (0, 0, 0, 0)$, and search for the contract targeting the good types by solving the maximization problem of the lead bank:

$$\max_{\{x_G, R_{G,L}, R_{G,M}, \mathcal{A}_G\}} x_G p R_{G,L} - \mathcal{A}_G \tag{1}$$

subject to

$$x_G(pR_{G,M} - 1) + \mathcal{A}_G \geq 0, \tag{2}$$

$$x_G q R_{G,L} - \mathcal{A}_G \leq 0, \tag{3}$$

$$R = R_{G,L} + R_{G,M}, \tag{4}$$

$$x_G \in \{0, 1\},\ \mathcal{A}_G \leq A. \tag{5}$$

Condition (2) is the participation constraint of the syndicate members; condition (3) is the mimicking constraint of the lead bank representing a borrower of the bad type.

To begin with, $x_G = 1$ otherwise the contract would yield a zero payoff for L, despite a good-type firm holding a positive-NPV project.

Since the symmetric information contract cannot be offered without having the bad type mimicking the good type, L will set the higher value of $R_{G,L}$ that satisfies a binding condition (3). It follows that $qR_{G,L} = \mathcal{A}_G$.

[9] We adapt the signalling model in Tirole (2006), Chapter 6, to our context.

Plugging $R_{G,L} = \mathcal{A}_G/q$ into the maximand, we obtain:

$$\mathcal{A}_G \left(\frac{p}{q} - 1 \right), \tag{6}$$

which increases in $\mathcal{A}_G$; thus, $\mathcal{A}_G = A$ (L commits its entire funds in the loan) and $R_{G,L} = A/q$. □

First, the lead bank wants to pledge all its funds as a signal that it is confident about the good firm's future returns. Second, the reward, $R_{G,L}$, is determined by the mimicking condition of the bad type: the lead bank picks the largest repayment that makes the bad type indifferent between accepting the contract targeting the good type and remain inactive. Finally, the good-type contract can be interpreted as a debt contract featuring M transferring $1 - A$ upfront and getting $R - A/q$ if the project succeeds. The firm goes bankrupt if the project fails.

To sum up, without common ownership, the lead bank will underwrite the loan by committing $\mathcal{A}^* = \mathcal{A}_G = A$. The syndicate members will ask for an interest rate equal to $1 + r^* = R - A/q$.

Funding with common ownership Consider now the case in which the lead bank attaches a weight $\kappa \geq \underline{\kappa}$ on commonly owned potential syndicate members. Specifically, there is a fraction $\theta \in (0, 1)$ of commonly owned potential syndicate members (M_{Co}) and a complementary fraction $(1 - \theta)$ that are not commonly owned with the lead bank (M_{NCo}).

We follow the literature (Padilla and Pagano, 2000) and assume that, before the negotiations take place, the lead bank L decides whether to commit to share with M_{Co} the information on the type of borrower it is representing. Only the commonly owned investors M_{Co} observe this choice. Then, L decides the order by which it negotiates with M_{Co} and M_{NCo}, considering that, if it commits to share information, the negotiations with M_{Co} will take place under symmetric information. In line with our empirical application, the offer formulated by the lead bank is public and the outcome of the negotiations is observable. Moreover, the lead bank is restricted to offer the same contract to M_{Co} and M_{NCo} (so that $R_{G,M} = R_{G,M_{Co}} = R_{G,M_{NCo}}$). Finally, when indifferent, the lead bank will prefer to do information sharing.[10]

In the following proposition, we show that if information sharing takes place in equilibrium, the symmetric information contracts are offered by the lead bank and all investors accept.

[10]This captures, in a reduced form, the reputational cost of not sharing information with commonly owned investors in a model with multiple interactions between the lead bank and potential syndicate members.

Proposition 2. *With high common ownership, the lead bank commits to share its information on the type of the borrower with M_{Co}. At equilibrium, L first approaches the commonly owned investors by offering $(x_B, R_{B,L}, R_{B,M}, \mathcal{A}_B) = (0, 0, 0, 0)$ and*

$$(x_G, R_{G,L}, R_{G,M}, \mathcal{A}_G) = (1, R - 1/p, 1/p, 0),$$

and all potential syndicate members accept.

Proof. Consider first the case in which the information about the borrower type is shared between L and M_{Co}. If it approaches the commonly owned investors, the negotiations take place under symmetric information. We then show that a lead bank representing a good type wants to minimize the reward offered to potential syndicate members ($R_{G,M}$) and the amount it invests in the loan ($\mathcal{A}_G$). Specifically, this lead bank's profits are

$$x_G p R_{G,L} - \mathcal{A}_G + \theta\kappa\pi_{M_{Co}}, \tag{7}$$

where $R = R_{G,L} + R_{G,M}$, and $\pi_{M_{Co}} \equiv x_G(pR_{G,M} - 1) + \mathcal{A}_G$ denotes the profits of the commonly owned potential syndicate members. Plugging $R_{G,L}$ and $\pi_{M_{Co}}$ into L's profits, we obtain

$$x_G p[R - (1 - \theta\kappa)R_{G,M}] - (1 - \theta\kappa)\mathcal{A}_G - \theta\kappa x_G.$$

Since $\theta\kappa < 1$, this expression strictly decreases in $R_{G,M}$ and $\mathcal{A}_G$. Hence, L will offer M_{Co} the symmetric information contracts: $x_B = 0$, $x_G = 1$, $\mathcal{A}_G = 0$ and $R_{G,M} = 1/p$. This arrangement would satisfy M_{Co}'s binding break-even condition,

$$x_G(pR_{G,M} - 1) + \mathcal{A}_G = 0,$$

and maximize the profits in Expression (7); thus, M_{Co} accept. When approached by L, M_{NCo} observe the decision taken by M_{Co} and know that, if they latter accepted, the borrower represented by the lead bank must be of the good type. They update the priors on the borrower's type accordingly, and also accept the offer.

Consider now the case in which the lead bank commits not to share its private information with M_{NCo}. This scenario is equivalent to the one in which the lead bank decides to negotiate with M_{NCo} first. In both, the negotiations happen under asymmetric information. Similarly to what we do in Proposition 1, we set $(x_B, R_{B,L}, R_{B,M}, \mathcal{A}_B) = (0, 0, 0, 0)$, and solve for the contract targeting the good types by solving L's maximization problem.

Different from Proposition 1, L's profits,

$$x_G p R_{G,L} - \mathcal{A}_G + \theta\kappa\pi_{M_{Co}}, \tag{8}$$

and the mimicking constraint,

$$x_G q R_{G,L} - \mathcal{A}_G + \theta\kappa\pi_{M_{Co}} \leq 0,$$

take into account that a fraction of potential members is commonly owned. However, the feasibility conditions ($x_G \in \{0,1\}$, $\mathcal{A}_G \leq A$, $R = R_{G,L} + R_{G,M}$) and investors' participation constraint,

$$x_G(pR_{G,M} - 1) + \mathcal{A}_G \geq 0, \tag{9}$$

stay the same.

By the same arguments as in the asymmetric information problem of Proposition 1, the contract to the good types optimally sets $x_G = 1$, $\mathcal{A}_G = A$ and a value of $R_{G,L}$ that satisfies a binding mimicking constraint. Plugging the resulting value of $R_{G,L}$ into Expressions (8) and (9), we find that the condition ensuring M's participation implies that the symmetric information profits are larger than the profits with asymmetric information and common ownership. Hence, the lead bank will commit to share information and negotiate with M_{Co} under symmetric information before approaching M_{NCo}.

Finally, the lead bank representing the bad borrower will not obtain financing both with and without information sharing; thus, it will be indifferent and decide in favor of sharing its information under our tie-breaking rule. □

The lead bank will channel its information about the borrower's type to the commonly owned syndicate members. This happens because information sharing allows the lead bank to save on costly signaling. In line with the evidence in Section 2.2, common ownership makes credible information sharing possible via a network of overlapping directors. In models with costly information sharing, communication happens in equilibrium if the cost of transmitting information is sufficiently small (see Jappelli and Pagano (2002) for a review of the literature). In our model, the portfolio investments that are necessary to achieve common ownership are sunk at the time in which lenders decide on whether to communicate. This makes communicating the borrower type to the commonly owned members the optimal strategy for the lead bank.

With information sharing, only the good projects will be funded ($x_G = 1$,$x_B = 0$), the loan is fully underwritten by the members of the syndicate ($\mathcal{A}^{**} = \mathcal{A}_G = 0$) in exchange of an interest rate equal to $1 + r^{**} = 1/p$. In analogy to the case without common

ownership, the contract targeting a good type can be interpreted as a debt contract in which the members of the syndicate transfer 1 upfront and get $1/p$ in the case of project success or else the firm goes bankrupt.

3.2 Empirical predictions

The following proposition lists the empirical predictions of the model.

Proposition 3. *Comparing the lending conditions ($1+r$ and $\mathcal{A}$) with common ownership and without common ownership, we find that:*

1. *The interest rate charged by syndicate members is lower with common ownership than without common ownership.*
2. *The lead bank commits more funds in the loan without common ownership than with common ownership.*
3. *The standard deviation of the loan returns to the syndicate members is lower with common ownership than without common ownership.*

Proof. For the first bullet point, note that

$$r^* - r^{**} = R - \frac{A}{q} - \frac{1}{p} > 0 \tag{10}$$

$$\iff A < \frac{q(pR-1)}{p} \tag{11}$$

follows from Assumption 1.

The second bullet point directly follows from $\mathcal{A}^{**} = 0 < A = \mathcal{A}^*$.

For the third bullet point: given $r \in \{r^*, r^{**}\}$, the formula for the variance of the project's returns is

$$Var(R) = E[r^2] - E[r]^2 = pr^2 - (pr)^2, \tag{12}$$

which is increasing in r for all $(1-p)r > 0$. So the standard deviation of returns is larger without common ownership. □

First, in line with intuition developed after Proposition 2, absent common ownership, the separation of types requires that the good firm be less greedy than with common ownership, and promise higher rewards to the syndicate members. Second, to achieve separation, the lead bank representing a firm with a good project signals its type by committing A in the loan. The lead bank thus conveys the quality of the project it is

issuing by means of a "dissipative signal" (Tirole, 2006). Finally, due to lower interest rates, the returns' standard deviation will be lower with common ownership.

3.3 Discussion

Without common ownership, the presence of asymmetric information implies that the lead bank must signal the good firm's type to the potential members by committing its funds in the loan. Since signaling is costly, the interest rate paid will be higher than with common ownership and symmetric information. These results require that there is truthful information sharing with common ownership. In our model, this interpretation is supported by the evidence in Section 2.2: commonly owned banks share a network of directors that facilitates the channeling of information (in essence, they play the role of the information transmission technology in our model). However, even absent these overlapping directors, large degrees of common ownership may be sufficient to guarantee the credibility of the information transmitted by the lead bank. This interpretation is supported by results in the theoretical literature on cheap talk: the sender of private, soft information will truthfully communicate such information if its preferences are aligned with the receivers' (Crawford and Sobel, 1982; Dessein, 2002). As the lead bank and the syndicate members own a stake in their respective profits, common ownership aligns their preferences.

The predictions of our model are derived under the assumption that the lead bank holds private information on the expected return of the borrower. We would find the same qualitative results if the lead bank had superior information on the cost of monitoring the firm (Sufi, 2007). If the monitoring cost is unobservable by potential syndicate members, the lead bank needs to retain a share of the loan to signal that it has an incentive to put effort. Moreover, costly signaling would cause a lower reward to the lead bank, and hence a larger reward to the members of the syndicate. Thus, the predictions of this alternative model would be the same as those we find in Proposition 3.

In principle, other dissipative signals could be used to achieve separation of types without common ownership. For example, the borrower could accept shorter maturities or pledge collateral. However, the non-price dimensions of syndicated loans are set before the marketing stage – that is, before syndicates form at the facility level. Moreover, except for maturity, those non-price attributes do not to vary across facilities. Any correlation with common ownership would therefore be spurious or non consequential.

Finally, the separating equilibrium in Proposition 1 is not the unique equilibrium of the game with asymmetric information. Other pooling equilibria that resemble an option contract can exist. In such equilibria, the contract has the lead bank choosing between accepting a contract in which it is rewarded only in the case of success, and a contract

that has an upfront lump-sum payment A, and no investment. In practice, the bad firm, which chooses the second option, is bribed to go away and not invest.[11] Our focus on the separating equilibrium in Proposition 1 is motivated by the fact that such option contracts are not offered in syndicated lending. Nonetheless, they still satisfy our prediction on the lead bank's commitment of A in the loan. The prediction on the interest rate, instead, is satisfied under stronger parametric conditions on the value of the return R.

4 Data

Our sample is constructed in two steps: in the fist step, we assemble a sample of firm-bank-loan-facilities observations between 1990 and 2013. In the second step, we combine our data with information from Thomson Reuter's SEC 13F filings to determine the common investors of the lead bank and the syndicate members within a loan.

4.1 Sample construction

Syndicated Loans Our primary data source is the Loan Pricing Corporation's (LPC) DealScan database which identifies bank-firm relationships. Dealscan contains detailed information on the loan, such as the interest rate paid to the lender group measured in basis points (the all-in drawn spread, which is the sum of the spread of the facility over LIBOR and any annual fees), loan size, loan type (credit line or term loan), purpose (mainly corporate, excluding leveraged buyout), and the presence of collaterals. We restrict the sample to loans issued by commercial banks incorporated in the U.S. to U.S. non-financial firms between 1990 and 2013.

We identity the participants in a syndicate at the loan level. Following Ivashina (2009), we classify a bank as lead bank if its Lender Role field in DealScan is one of the following: administrative agent, agent, arranger, book-runner, coordinating arranger, lead arranger, lead bank, lead manager, and mandated arranger.[12] We then use linking tables from Chava and Roberts (2008) and Schwert (2018) to merge the loan data with borrower and lender characteristics from Compustat, including borrower size, profitability and rating (investment-grade, high-yield and unrated) and lender size and profitability.[13]

[11] See Tirole (2006) Chapter 6 for details.

[12] In the residual case in which no lead bank or multiple ones are identified, we attribute the role of lead bank to the banks for which the field "Lead Arranger Credit" is marked with "Yes".

[13] Schwert (2018) hand-matches DealScan lender names with Compustat GVKEYs for all lenders with at least 50 loans or at least $10 billion in loan volume. The matching table takes into account bank subsidiaries and bank mergers during the sample period.

Common Ownership To measure common ownership, we use three sources. The first one is the Thomson Reuters s34 database, which consolidates information from the mandatory 13F SEC filings that all institutions with at least $100 million of assets under management have to report at quarterly frequency. We complement the Thomson Reuters s34 data, when possible, with scraped 13F holdings from Backus et al. (2021b). We are careful to aggregate Blackrock holdings filed separately under different entities (Ben-David et al., 2018). Finally, we collect data on shares outstanding from the Center for Research in Securities Prices (CRSP), which we merge to historical CUSIP codes of banks. Our resulting sample allows us to determine which banks within a loan relationship have common institutional investors and the extent of such overlapping ownership at the loan-facility level.

4.2 Measures of common ownership

The literature proposes several measures of common ownership, such as the Modifed Herfindahl-Hirschman Index (MHHI) developed by O'Brien and Salop (2000), the GGL measure advanced by Gilje et al. (2020), or the measure based on a production function approach in Newham et al. (2018), which implicitly assumes that investors actively engage in decision making. We adopt the profit weights approach based on the theory of partial ownership developed by Rotemberg (1984). This approach has several merits. It avoids the need of defining product markets and a specific competitive conduct such as Cournot (as in the MHHI). It also allows for players' strategic interactions, a feature that is not present in GGL. Finally, different from Newham et al. (2018), our approach assumes that it is the lead bank that takes shareholders' portfolio interests explicitly into consideration. In the Appendix, we replicate our main analysis using alternative proxies for common ownership obtaining similar results.

As in Rotemberg (1984), we assume that the lead bank maximizes a weighted average of shareholder portfolio profits. To construct the profit weights, we rely on O'Brien and Salop (2000). Each lead bank a places a weight κ_{ab_i} on the profit of each syndicate member bank in facility i (b_i) that is overlapping in ownership:

$$\kappa_{ab_i} = \frac{\sum_{s \in S} \gamma_{as} \beta_{b_i s}}{\sum_{s \in S} \gamma_{as} \beta_{as}}, \tag{13}$$

where S is the set of shareholders of lead bank a, and γ and β are, respectively, the voting and cash-flow rights of each investor s. These weights capture the importance to each lead bank of a dollar of profit generated by the syndicate members. We follow the vast majority of the literature and assume that one-share corresponds to one-vote

(proportionality of voting rights): $\gamma_{as} = \beta_{as}$ and $\gamma_{b_i s} = \beta_{b_i s}$.[14]

Given Equation (13), the average weight that the lead bank a has on the profit of other syndicate members in each facility i is:

$$CO_{ia} = \frac{1}{B_i} \sum_{b=1}^{B_i} \kappa_{ab_i}, \tag{14}$$

where $B_i \in [1, \overline{B}]$ is the number of syndicate members in each facility i. We consider other choices to aggregate profit weights between the lead bank and members at facility level, such as median and mode: estimation results remain unchanged. Finally, we repeat the same exercise to determine the degree of common ownership between (i) borrowing firms and banks; (ii) member to lead arranger; (iii) participating banks within each loan relationship. The first measure will be an additional control to account for the presence of common and cross-ownership between vertically related firms. The second and third measures will be useful to run falsification tests of our hypotheses.

Following Backus et al. (2021b), we decompose the profit weights in Equation (13) to study the sources of common ownership variation at the facility level. Let $IHHI_a = \|\beta_a^2\|$ be the Herfindahl-Hirschman Index for the investors in company a. Define $\cos(\beta_a, \beta_{b_i})$ as the cosine similarity between vectors a and b_i, representing the cosine of the angle between the positions that investors hold in a and those that investors hold in b_i. Backus et al. (2021b) show that:

$$\kappa_{ab_i}(\beta) = \underbrace{\cos(\beta_a, \beta_{b_i})}_{\text{overlapping ownership}} \cdot \underbrace{\sqrt{\frac{IHHI_{b_i}}{IHHI_a}}}_{\text{relative IHHI}}. \tag{15}$$

The first term is the overlapping ownership. It captures the similarity in investor positions: for investors holding positions in both the lead bank a and a syndicate member bank b_i, a higher position will determine a smaller angle with cosine similarity approaching one. The second term captures the relative concentration of investors. Ceteris paribus, if the lead banks has fewer, larger, investors, then the value of $IHHI_a$ is large, control rights are relatively expensive, and profit weights $\kappa_{ab_i}(\beta)$ smaller. Conversely, if the lead bank has many small investors, the value of $IHHI_a$ is will be small, control rights relatively cheaper, and profit weights $\kappa_{ab_i}(\beta)$ larger.

[14] See Backus et al. (2021b) for a discussion on the importance of the one-share one-vote assumption and other measures of common ownership.

4.3 Summary Statistics

Table II provides the summary statistics: our final sample includes 15,688 loans granted to 4,529 firms. We identify 66 lead banks. The average syndicate size is of 8 members. Syndicates extend loans of $934 million on average. Every loan comprises a number of tranches called facilities: our unit of observation is at this granular level. On average a syndicated loan consists of 1.9 facilities. The average facility spread is 191 basis points and the average amount $544 million. Approximately 52% of the facilities are secured by a collateral. Most of the facilities in our sample are credit lines (67%).[15] On average, lead banks retain 21% of the facility amount: this variable is reported in around one third of the facilities in the sample.

Common Ownership Patterns In the banking sector, the four largest asset managers (Blackrock, Vanguard, State Street and Fidelity) hold together around 20% of the four largest U.S. commercial banks' shares. Figure 1 documents the striking increase in common ownership over time, confirming the findings of previous studies (Azar et al., 2018; Backus et al., 2021b). We calculate profit weights at facility level: on average, lead arrangers have a weight of 0.68 on the profits of the other syndicate members, with an increase from 0.37 in 1990 to 0.79 in 2013.

To interpret these patterns, we use the profit weights decomposition into overlapping ownership and relative lender concentration: see Equation ((15)). Figure 2 shows the results of such decomposition between 1990 and 2013. We document that control rights in the lead bank become relatively cheaper over time, driving the growth in profit weights. Panel (a) depicts the increase in profit weights, $\kappa_{ab_i}(\beta)$, over time. Panel (b) shows that cosine similarity, $\cos(\beta_a, \beta_{b_i})$, is, as expected, higher at high levels of common ownership and increasing over time. Panel (c) depicts the relative concentration of lenders, $\frac{IHHI_{b_i}}{IHHI_a}$, and Panel (d) represents the average concentration level of the lead banks only, $IHHI_a$. Taken together, Panel (c) and (d) document that, while relative concentration between bottom and upper quintile of common ownership does not differ very much, investors' concentration for the lead banks is much lower at the top quintile of common ownership and clearly decreasing over time relative to the bottom quintile. With the lead bank having many small investors, $IHHI_a$ will be small and control rights cheaper. This is driven, in part, by the growth of retail shares at higher levels of common ownership: as retail investors do not have incentives to engage in active governance, they leave more

[15] In the summary statistics, we present two aggregate types: credit lines and term loans. In the data, we observe more granularity, with different types of term loans (A, B, C, and higher designations). We account for these types in the empirical application, using the following categories: credit line, term loan A, term loan B, and others as the residual category. Lim et al. (2014) use a coarser aggregation, considering all facilities with designation B or higher as term loan B.

room for common owners to influence the lead banks' strategies.

A variance decomposition for all lead bank-member pairs of profit weights reveals that around 70% of the variation in profit weights comes from overlapping concentration, and relative investor concentration never falls below 30%. Investors' concentration has a sizeable impact in shaping the variation in profit weights both in the cross section and over time: at the lowest quintile of common ownership, institutional investors tend to be large and undiversified, thus the lead banks put more weight on their own profits.

Finally, in Table III we regress investors' shares on our measure of cosine similarity, controlling for their level of relative concentration. We verify that high levels of overlapping ownership are associated to higher shares of those investors: investors in each lead bank-member pair may therefore be more likely to engage in active and effective corporate governance thanks to their higher positions in both institutions.

Univariate Differences Table IV summarizes the univariate differences between facilities with high and low common ownership residualized on year fixed effects to account for the trends in the raw data. We label a facility with high common ownership if the average syndicate profit weight between the lead arranger and other syndicate members is in the upper quintile of the distribution.

On average, facilities with high common ownership display lower spreads, with a statistically significant difference of about 33 basis points, and a lower standard deviation of the returns. These facilities are characterized by a smaller amount retained by the lead bank, and are less likely to be secured by collaterals. Moreover, there are no statistically significant differences between borrowers across the low and high common ownership facility groups in terms of riskiness and profitability (as measured by default probability, stock volatility and ROA), except for a better ability of future loan repayment for borrowers in facilities with high common ownership (as measured by the interest coverage ratio). Although these patterns are broadly consistent with the predictions of the model, they may be driven by confounding factors like, for example, differences in borrower characteristics (observable or not). To control for these factors, we turn to the multivariate analysis in the next section.

5 Estimation and Results

We now specify and estimate a model to investigate whether the three predictions of Proposition 3 are verified in the data. In our model, common ownership affects the terms of syndicated loans by facilitating the transmission of information between the lead bank and the syndicate members. We express the outcomes of interest as a function of a

common ownership measure (CO) and other exogenous demand and supply covariates (X):

$$Outcome = \beta_0 + \beta_1 CO + \beta_2 X + \varepsilon, \tag{16}$$

where the dependent variable will be specified as: (i) the interest rate; (ii) the amount retained by the lead bank for each facility; (iii) the standard deviation of loan returns to the syndicate members. The coefficient of primary interest is β_1, the parameter measuring the impact of common ownership. Our estimated β's do not estimate neither parameters of the demand curve nor those of the supply curve, but instead the effect of each covariate on the equilibrium outcomes.

For each outcome variable, we first present the empirical specification. We then discuss the identification strategy, highlighting the key sources of identifying variation in the data. Finally, we present the results.

5.1 Interest rates

According to Prediction 1 of Proposition 3, the interest rate paid to the syndicate members will be lower at higher levels of common ownership. We test the prediction by estimating the following equation:

$$Spread_{iat} = \beta_0 + \beta_1 CO_{iat} + \beta_2 X_{iat} + \varepsilon_{iat}, \tag{17}$$

where the dependent variable $Spread_{iat}$ is the all-in-drawn spread paid to syndicate members, the credit spread over LIBOR plus annual fees of facility i arranged by bank a in quarter t. The variable of primary interest, CO_{iat}, is the average weight that the lead bank a puts on the profit of other syndicate members, as defined in Equation (14). Prediction 1 translates into the prediction that the coefficient β_1 is negative when common ownership is high enough.

The vector of variables X_{iat} includes an extensive set of controls related to (i) the loan and the facility; (ii) the borrower; (iii) the lender. We account for relations of common ownership between lenders and borrowers: under the lens of a vertical integration model, common ownership between lenders and borrowers may result in lower prices for the borrower. Other loan and facility-related controls include facility amount, number of participants, arranger's past relations with syndicate participants and with the borrower, the presence of collaterals in the facility, and its maturity. The rationale of using the facility amount and other non-pricing features of the loans as controls is that those characteristics are fixed before the syndication process. If we remove those controls, our estimates are essentially unchanged. We also control for the three-month LIBOR rate

at origination as the literature documents a relation between LIBOR and loan spreads (Roberts and Schwert, 2020). Borrower-related controls include borrower's size measured in assets, profitability, and a measure of leverage defined as book debt over total assets. Finally, lenders' related variables include their size, capital and profitability. The full set of controls X_{iat} is listed in Table A2.

In addition to our time-varying set of controls, we employ multiple fixed-effects to difference out alternative interpretations such as confounding effects of demand and supply variations. First, we account for variation in facility type and loan purpose. Second, we include in our baseline specification, Equation (17), industry-year-quarter fixed effects to control for aggregate variation in demand for syndicated loans in each sector, as well as aggregate time-varying propensity towards risk in each sector. Third, borrower fixed effects account for unobserved time-invariant heterogeneity across borrowers. Finally, to capture time-invariant supply factors, for example the fact that the lead arranger may specialize in loans with specific features or hold a certain reputation, we add lead bank fixed effects.

Our coefficient of primary interest, the one on common ownership, is mainly identified by the cross sectional variation that arises from differences in the composition of the syndicate both across facilities and across loans. As we use quarter-year fixed effects, interacted with the industry in which the borrower operates, the coefficient is identified by the within variation in common ownership among facilities and loans that differs from the average common ownership level faced by borrowers in a certain industry and period. Persistent differences in common ownership across borrowers and lead arrangers are absorbed by our fixed effects at borrower and lead arranger level.

While our set of controls and fixed effects is very extensive, we cannot rule out the possibility that variation in spread associated to common ownership may reflect omitted characteristics, for example related to borrower risk, that systematically correlate with both prices and common ownership. To address this concern, we focus on pricing differentials between different facilities of the same type *within* a loan with low and high levels of common ownership: this method of measuring the effect of common ownership on prices is unlikely to be affected by omitted characteristics. This identification strategy was developed by Ivashina and Sun (2011) and later adopted by Lim et al. (2014). As a credit event on one or more facilities within a loan triggers the default on the entire loan, facilities in the same loan essentially reflect the same underlying risk characteristics. We control for any other remaining difference across facilities of the same type that may influence their pricing: their size, maturity, and the presence of collaterals.

To assess the importance of each source of variation, we regress our common ownership measure on all the covariates included in the main specification, and then partition the

variance of the residual into three components: (i) variance in industry-year-quarter, borrower, lead arranger, facility type and loan purpose dummies; (ii) variance across loans; (iii) variance across facilities within a loan. We find that the first component explains around 66.5% of the total variance in common ownership: this is the portion of variance absorbed by our fixed effects and time-varying controls. Variation in common ownership across loans and facilities, after accounting for the fixed effects and the controls, explain 27.6% of the variance in common ownership. The remaining 5.9% comes from differences in common ownership within loans attributable to variation in common ownership across facilities.

Results Panel (a) of Table V presents the estimation results for the coefficients of primary interest. The full results from estimating this specification are presented in Column (4) and (5) of Table A4 in the Appendix. Column (1) of Table V reports the effect of our common ownership measure on prices without regard for non-linearities of the impact. Coefficient estimates indicate that an increase of one standard deviation in common ownership is associated with a lower spread of $0.2 \times 26.78 = 5.34$ basis points.

To understand how price reductions vary across the range of common ownership, we discretize our common ownership measure into five indicator variables corresponding to the quintiles of its support: CO^1_{iat} $(0.06 < CO_{iat} < 0.46)$; CO^2_{iat} $(0.46 < CO_{iat} < 0.62)$; CO^3_{iat} $(0.62 < CO_{iat} < 0.75)$; CO^4_{iat} $(0.75 < CO_{iat} < 0.84)$; CO^5_{iat} $(0.84 < CO_{iat} < 1.20)$. Column (2) of Table V shows that reductions in spread are relevant only for high levels of common ownership (quintile 4 to 5, corresponding to 41% of the loans in our sample), and those reductions are monotonically increasing in common ownership. Assuming no changes in spread for the omitted category (CO^1_{iat}), the point estimates represent the average change in spread for loans in each quintile. Our results are not only statistically, but also economically significant: within a quintile, a change in common ownership in a facility from the minimum to the maximum level reduces the price by roughly 10 basis points. The average loan spread in quintile 4 and 5 of common ownership is around 197 points.

The Appendix contains the results of several robustness tests. Table A3 reports the same empirical specification using an alternative definition of common ownership as the average of the minimum commonly held shares between the lead arranger and the syndicate members (see Equation (2) in Newham et al. (2018)): the parameter estimates are remarkably similar in magnitude. Our results are also robust to the inclusion of different sets of fixed effects, as reported in Table A4. In particular, in Column (6) we include lead-year-quarter fixed effects rather than additive lead bank and year-quarter fixed effects. The interaction rules out sorting based on some unobservable variation in the risk

preferences in each lead arranger: the resulting coefficient has roughly the same magnitude. In Column (7) we consider borrower-year fixed effects to control for unobserved time-varying borrower heterogeneity: estimates indicate an even larger magnitude of the reduction in spread associated to high common ownership.

Within-loan estimates We estimate the effect of common ownership on the pricing of facilities of the same type *within* a loan. We have 302 loans with facilities of the same type in the same loan. We estimate Equation (17) on this subsample; results are reported in column (1) and (2) of Table V, Panel (b). Differences in spread between facilities of the same type with low/high common ownership cannot be attributed to correlation between common ownership levels and firm-level unobservables driving the spread. The estimates confirm again our hypothesis of price reduction as common ownership increases. Our estimates imply a spread reduction of even bigger magnitude with respect to the above estimation: within a quintile, a change in common ownership in a facility from the minimum to the maximum level of common ownership reduces the spread by roughly 20 basis points.

Finally, our sample contains 2,022 loans in which a borrower issues one or more loans, in the same year, with more than one facility type, non necessarily from the same loan. Table V reports the coefficients estimates of Equation (17) on this subsample. The estimated decrease in price determined by common ownership is similar to the within-loan specification.

In sum, both the estimates based on cross-sectional variation and within-loan variation are consistent with Prediction 1 of Proposition 3.

5.2 Funds committed by the lead bank

Prediction 2 of Proposition 3 says that, at higher levels of common ownership, information sharing between the lead bank and the members of the syndicate implies that the lead bank detain a lower share of funds for each facility in the loan. We test Prediction 2 by estimating the following equation:

$$Percent\ Lead\ Amount_{iat} = \beta_0 + \beta_1 CO_{iat} + \beta_2 X_{iat} + \varepsilon_{iat}, \tag{18}$$

where the dependent variable is the percent of facility i's amount detained by lead bank a in quarter t. As before, X_{iat} includes an extensive set of controls related to (i) the loan and the facility, (ii) the borrower and (iii) the lender. As before, we account for variation in facility type and loan purpose; we include industry-year-quarter fixed effects to control for aggregate variation in demand for syndicated loans in each sector, and use lead bank

fixed effects to capture time-invariant supply factors.[16]

Prediction 2 implies that β_1 is negative. Table VI presents the coefficient estimates of Equation (18). Column 1 reports the effect of our common ownership measure on the share of loan retained by the lead bank without regard for the possible non-linearities of such impact. Coefficient estimates indicate that an increase of one standard deviation in common ownership as measured by CO_{iat} implies a 0.64 percentage point decrease in the amount retained by the lead bank, holding all other variables constant at their mean values. As above, we discretize our common ownership measure into five indicator variables corresponding to the quintiles of its support to account for non-linearities. Column 2 of Table VI reports that reductions in the funds committed by the lead bank are relevant only for high levels of common ownership. Assuming no effect on the amount retained by the lead for the omitted category (CO^1_{iat}), the point estimates in Table VI represent the average percent point change in the share of facility retained in each quintile. We find statistically significant decreases in quintiles 3 to 5; within a quintile, an increase in common ownership from the minimum to the maximum level implies a reduction in the amount of facility retained by the lead corresponding to roughly 1.7 percentage points in quintile 3 and 2.7 percentage points in quintile 4 and 5. Lead arrangers retain on average 21% of the facility amount, therefore the impact of common ownership on loan retained is sizeable.

Within-loan estimates Similarly to above, we test our the hypothesis by restricting our attention to the relatives differences between facilities within the same loan: thanks to such identification strategy, measuring the effect of common ownership on the portion of funds committed by the lead arranger is unlikely to be affected by unobserved firm-level heterogeneity, like the risk of default. Before presenting the estimation results, we need to address the fact that information on the share retained by the arranger is often missing, as well documented in the literature (Ivashina, 2009); when restricting our sample to loans with multiple facilities of the same type, we face a problem of small sample size and, as a consequence, low statistical power. We recover the missing shares using multiple imputation methods. Because of the high fraction of missing information, we only apply the technique to loans for which (i) we have a sufficient number of observations for the auxiliary variables; (ii) only some facilities in the loan have missing information on the amount retained by the lead arranger.[17] Our final sample contains only 100 loans with multiple facilities of the same type in a loan for which we are able to recover the percent

[16] As well known in the literature, information on the share retained by the lead arranger is available for only 30% of the facilities in our sample; we therefore do not include borrower-level fixed effects because of overfitting concerns given the limited sample size.

[17] Chodorow-Reich (2014) and Darmouni (2020) use imputation techniques on datasets of the same type to recover the missing information on the share retained by the arranger.

of loan retained by the lead. We estimate Equation (18) on this subsample. Results are reported in column (1) and (2) of Table VI, Panel (b). Again, the negative sign of the coefficient estimates points to a decrease in the share of the loan retained by the lead arranger; however, the size of our sample is insufficient to detect a statistically significant effect.

To overcome the issue of power, we turn to multiple loans issued by a borrower, in a given year, with more than one facility type. Our sample presents 685 loans with these characteristics. Our coefficients are identified by variation in the degree of common ownership across facilities of the same type in one or more loans issued by a borrower in a given year. Table V reports the coefficients estimates of Equation (18) on this subsample. The results confirm a decrease in the retained amount determined by common ownership: the magnitude of the coefficient estimates is similar to the one obtained in the within-loan specification; the coefficients are now statistically significant as we have more observations.

In sum, we confirm our hypothesis of reduction in the amount retained by the lead for each facility as common ownership increases.

5.3 Standard deviation of loan returns

According to Prediction 3 of Proposition 3, the standard deviation of the loan returns to the syndicate members is lower at higher levels of common ownership. We test the hypothesis by estimating the following equation:

$$Stand.Dev.\ Spread_{jat} = \beta_0 + \beta_1 CO_{jat} + \beta_2 X_{jat} + \varepsilon_{jat}, \tag{19}$$

where $Stand.Dev.\ Spread_{jat}$ denotes the standard deviation of the all-in-drawn spread across facilities within loan j arranged by bank a in quarter t. The unit of observation is therefore loan-bank-firm rather than facility-loan-bank-firm as before. Common ownership is measured as the average profit weights across facilities within the loan j. The coefficient β_1 measures the effect of an increase in common ownership between members of the loan on the dispersion of the all-in-drawn spread.

Prediction 3 implies that β_1 is negative when common ownership is sufficiently high. Table VII presents the estimates of Equation (19) in column (1) and (2). An increase of one standard deviation in common ownership is associated with a 2.97 basis points decrease in the standard deviation of the spread. Given that the standard deviation of the spread equals to 21 basis point, such decrease corresponds to 14% of the total spread. In column (3) and (4), we redefine the dependent variable as the standard deviation in the price of loans issued by the same borrower in a year; coefficients estimates present the same sign and similar magnitude.

6 Other Results

6.1 Falsification Tests

We now present the results of two falsification tests: they both leverage on the testable implications of our hypothesis of common ownership as a mechanism of information transmission from the lead to the member banks.

Common ownership member-lead The first falsification test exploits the asymmetry in our measure of common ownership between pairs of banks: lead-member, κ_{ab_i}, and member-lead, κ_{b_ia}. Such asymmetry is a feature of our common ownership measure and results in the following testable implication: as only the lead arranger holds superior information on the borrower, the level of common ownership from the syndicate member to the lead arranger (κ_{b_ia}) should not impact the lending conditions once we control for the weight that the lead arranger puts on the profit of the syndicate member (κ_{ab_i}). As discussed in Backus et al. (2021b), such asymmetry is entirely driven by differences in relative investor concentration. In Appendix, we provide a decomposition of the profit weights member-lead into cosine similarity and relative lender concentration: see Equation (15). Figure 3 shows the results: Panel (a) shows that the cosine similarity member-lead is identical to lead-member, as reported in Figure 2. Panel (b) depicts the relative concentration of lenders in the measure of common ownership member-lead.

We estimate Equation (17) and Equation (18) by regressing both the all-in-drawn spread and the amount of loan retained by the lead on a measure of the average common ownership between lead arranger and syndicate member in a facility (CO_{ia}), as before, and a measure of the average common ownership between syndicate member and lead arranger in a facility (CO_{ib}). The expectation is that adding CO_{ib} should not impact the lending conditions. Column (3) and (4), Panel (a) of Table VIII show the results: in all specifications, the magnitude of the coefficient of common ownership lead-member (CO_{ia}) is unchanged. The coefficient of common ownership member-lead (CO_{ib}) is small in magnitude and not statistically different from zero.

Common ownership member-member The second falsification test turns to the level of common ownership between members. Our identification strategy relies on the presence of variation in common ownership between the lead bank and the syndicate members across facilities and loans: only the lead bank possesses superior information on the riskiness of the borrower (good or bad type). In presence of high common ownership, information sharing between the lead and the commonly owned members mitigates those information asymmetries, resulting in lower prices. We test our identification strategy by

conducting a falsification test. We select a sample in which common ownership between the lead and the members is low; we then compute a measure of common ownership between member pairs, rather than between lead-members. We estimate Equation (17) by regressing the all-in-drawn spread against the member-member common ownership measure. Panel (b) of Table VIII reports the estimated coefficients: common ownership between members does not appear to impact the pricing of facilities. We also re-estimate Equation (18) regressing our outcome variable against the measure of common ownership between member pairs. Column (3) and (4), Panel (b) of Table VIII reports the estimated coefficients. Again, common ownership between members does not impact the share of facility retained by the lead bank.

Overall, both tests constitutes an indirect confirmation that information sharing is effectively initiated by the lead bank when common ownership between the lead arranger and the members in high enough.

6.2 Heterogeneous Effects

In our analysis we have so far considered the overall effect of common ownership on the financing terms of syndicated loans. We expect that the role of common ownership will be stronger when information asymmetries are particularly pronounced. Following Sufi (2007), we consider two dimensions of heterogeneity in information asymmetry between the informed lead arranger and the uninformed syndicate members: the transparency of borrowers, proxied by their rating, and the reputation of borrowers, measured by their past access to the loan market.

Table IX reports the results of regressing the all-in-drawn spread against the common ownership measure for each subsample: rated versus unrated and new versus repeated borrowers. Panel (a) of Table IX shows that common ownership strongly impacts loan pricing when borrowers are opaque (unrated), and the effect is stronger with respect to more transparent borrowers (rated). Assuming no effect on the amount retained by the lead for the omitted category (CO^1_{iat}), the coefficient estimates represent the average percent point change in the share of facility retained in each quintile. For unrated borrowers, public firms without a credit rating, we find statistically significant decreases in quintiles 4 and 5; within a quintile, an increase in common ownership from the minimum to the maximum level implies a reduction in spread corresponding to 10.5 basis points in quintile 4 and 19.0 percentage points in quintile 5. The corresponding values for rated firms are much smaller: 6.5 basis points in quintile 4 and 10.2 in quintile 5. Panel (b) of Table IX shows that common ownership matters for borrowers whose reputation is less established. Those borrowers have almost no history in the loan market; the lead arranger carrying out the due diligence will be more likely to hold an information advantage over the un-

informed syndicate participants. For borrowers forming new relations with the lead in the market, we find statistically significant decreases in quintiles 3 to 5; within a quintile, an increase in common ownership from the minimum to the maximum level implies a reduction in spread corresponding to 9.0 basis points in quintile 3, 17.9 basis points in quintile 4, and 23.0 basis points in quintile 5. In contrast, common ownership does not impact the spread of repeated borrowers.

6.3 Common Ownership and Syndicate Participation

Our variable of interest, common ownership, is a function of the syndicate structure, namely the set of lenders participating in the syndicate. As the lenders decision to enter the syndicate is not random and may depend, among other factors, on the level of common ownership with the lead arranger and other unobservables collected in the error term, we extend our model to account for this form of self-selection. We assume that the utility maximization problem of potential members can be characterized by a reservation interest rate (spread) or reservation return. The reservation interest rate will depend on the characteristics of the member, among which his assessment on the riskiness of the borrower, as follows:

$$Spread^{r}_{iabt} = \gamma_0 + \gamma_1 \kappa_{iabt} + \gamma_2 X_{iabt} + \upsilon_{iabt}, \tag{20}$$

where κ_{iabt} is weight that the lead arranger a puts on the profit of each potential syndicate member b in facility i arranged in quarter t, as defined in Equation (13). Finally, X_{iabt} is a vector of controls including characteristics of (i) the potential member; (ii) the lead arranger; (iii) the loan and the facility; (iv) the borrower.

If the actual interest rate offered to the potential members is below the reservation interest rate, $Spread^{r}_{iabt}$, the potential member does not participate in the syndicate. The participation decision of potential member bank (p_{iabt}) is therefore:

$$\begin{aligned} p_{iabt} &= 1 \text{ if } Spread_{iat} - Spread^{r}_{iabt} > 0 \\ &= 0 \text{ if } Spread_{iat} - Spread^{r}_{iabt} \leq 0. \end{aligned}$$

The inequality can be expressed as follows:

$$\begin{aligned} p^{*}_{iabt} &= (\beta_0 - \gamma_0) + (\beta_1 \kappa_{iabt} - \gamma_1 \kappa_{iabt}) + \\ &\quad (\beta_2 X_{iabt} - \gamma_2 X_{iabt}) + (\varepsilon_{iabt} - \upsilon_{iabt}) \\ &= \delta_0 + \delta_1 \kappa_{iabt} + \delta_2 X_{iabt} + \eta_{iabt}. \end{aligned}$$

The participation equation is therefore:

$$p_{iabt} = 1[\delta_0 + \delta_1 \kappa_{iabt} + \delta_2 X_{iabt} + \eta_{iabt} > 0]. \tag{21}$$

The resultant outcome equation is:

$$\begin{aligned} Spread_{iat} &= \beta_0 + \beta_1 \kappa_{iabt} + \beta_2 X_{iabt} + \varepsilon_{iabt} \text{ if } p^*_{iabt} > 0 \\ &= \text{not observed if } p^*_{iabt} \leq 0, \end{aligned} \tag{22}$$

where we modify Equation (17) to use a more granular unit of observation at member-facility level rather than facility level as in the main specification.[18] Clearly, the error term η_{iabt} involves the unobserved determinants influencing the interest rate offered to the members ε_{iabt}. To account for correlation between unobservable drivers of participation and the resulting interest rate offered to the syndicate members, we assume a joint normal distribution for the two error terms:

$$\begin{pmatrix} \eta_{iabt} \\ \varepsilon_{iabt} \end{pmatrix} \sim N\left(0, \begin{pmatrix} 1 & \sigma_{12} \\ \sigma_{12} & \sigma_2^2 \end{pmatrix}\right).$$

We estimate the model using the standard Heckman two-step procedure. The joint normality of the errors implies that the error in the pricing equation, ε_{iabt}, is a multiple of the error in the participation decision equation (σ_{12}) plus some noise that is independent of the participation decision equation.

While the sample selection model is theoretically identified without any restriction on the regressors, we use exclusion restrictions to allow for identification of the parameters attributable to variation in the data rather than parametric assumptions. We argue that the following variables should impact participation, but should not affect the resulting prices: the characteristics of potential members, a variable capturing the portfolio similarity between the potential member and the lead (Euclidian distance), a dummy equal to one if the potential member had previous relations with the borrower. Interest rates are a function of a variety of determinants linked to the lead bank, the borrower and the loan, but the characteristics of potential members should not directly influence the final price. While the validity of the exclusion restrictions cannot be directly tested, we perform some sensitivity analyses and results do not change. Finally, all the variables included in the participation equation are also present in the outcome equation.

Table X presents the results without the correction for selection (Column 1) and with the correction (Column 2 and 3). Results from the selection model indicate that

[18] The dependent variable, $Spread_{iat}$, is set at facility level and does not vary across members of the same facility.

participation is not random. Panel (a) of Table X presents the results using the full sample of observations. In Column (2) we present the results of the participation equation. Potential members with higher common ownership with the lead bank are more likely to enter the syndicate, confirming that high levels of common ownership can mitigate information asymmetries: as those potential members may hold superior information than other uninformed participants, their reservation price is lower and they may be more likely to participate in the syndicate. Other statistically important drivers of participation include the level of common ownership between the potential member and the borrower (positive), and the portfolio distance between the lead and the member (negative).

We find evidence of negative selection, with a significant sample selection term, λ, and an implied correlation coefficient of 0.43: we have unobserved attributes that positively affect the probability of participating to the syndicate, but negatively affect the prices offered to the syndicate members. Qualitatively, these results do not appear to be very different from those without correction, especially with regard to the impact of common ownership on prices.

In Panel (b) of Table X we repeat the same analysis selecting the subsample of 302 loans with facilities of the same type in the same loan. In this setting, it is reasonable to assume that the decision of potential lenders to enter the syndicate and fund the loan essentially depends on the credit risk of the borrower. In contrast, the choice of the specific facility should mainly depend on lender-specific preferences. As a consequence, the composition of the syndicate across facilities within a loan should not depend on the degree of common ownership. Our intuition is verified in the data: common ownership is not a driver of participation in specific facilities of loans. The differences between the estimates with and without selection are practically small. The t-statistic on the coefficient of the selection term, λ, is statistically insignificant, and the implied correlation coefficient is practically zero. As a result, the two models lead to similar coefficient estimates.

7 Conclusion

We study the impact of common ownership in the syndicated loan market, focusing on the connection between the lead bank and the syndicate members. Our hypothesis is that common ownership may facilitate the transmission of private information on the borrowing firms between the lead bank and other members of the syndicate; common ownership is therefore a tool to ease information asymmetries.

We empirically document that in the syndicated loan market shared directors are more likely when common ownership increases: this positive association supports the idea of common ownership as an information transmission device. After, we develop a signaling

model in which a lead bank detains private information on the riskiness of a project while seeking funding to finance it. Signaling is costly in that it requires a larger commitment of funds by the lead bank. We solve the model under two scenarios: no common ownership, corresponding to asymmetric information, and high common ownership, corresponding to symmetric information. The model provides three empirical predictions: at higher levels of common ownership (i) the interest rate paid to the syndicate members is lower; (ii) the lead bank retains lower funds; (iii) the standard deviation of the loan returns to the syndicate members is lower.

We use data on the syndicated loan market to empirically verify these predictions and find clear empirical support for all of them. Our identification leverages on the differences in the level of common ownership between tranches of a loan, holding the risk of the underlying asset constant. An increase of one standard deviation in common ownership between the lead arranger and members of the syndicate is associated with a decrease equal to: (i) 9 basis points in interest rates; (ii) 0.64 percentage points in the amount retained by the lead; (iii) 2.97 basis points in the standard deviation of the spread. These results are robust to a variety of robustness and falsification tests.

Regulators recognize that common ownership can be conducive to the transmission of information regarding the borrower. We provide empirical evidence consistent with the presence of this flow of information and quantify the impact of common ownership on the contractual terms of the loan. More broadly, we provide a novel view on common ownership as a mechanism to mitigate the effects of information asymmetry. Given the pervasiveness of overlapping ownership across industries, future research analysing its impact in other contexts characterized by information asymmetry would be of relevant interest.

The table reports the OLS regression parameter estimates and t-statistics. The dependent variable is as an indicator equal to one if a pair of banks have a board connection. Distance Lead-Member is the portfolio distance between the lead bank and the syndicate participant in the previous four quarters, Relationship Lead-Member is the number of loans arranged by the lead bank where the member bank participated in the previous four quarters divided by the number of loans arranged by the lead bank in the previous four quarters. Standard errors are clustered by member bank. ***, **, and * correspond to statistical significance at the 1%, 5%, and 10% level, respectively.

The table reports the OLS regression parameter estimates and t-statistics. The dependent variable is the average share retained by the top 10 common shareholders in each lead bank, *Mean Share Top 10*. The covariate of interest is the average cosine similarity between the lead bank and other syndicate members, *Cosine Simil Quintile 1-5*. *Lead IHHI* is the Herfindal-Hirschman Index (HHI) for the investors in the lead bank. *Average Synd. Member IHHI* is the aveage Herfindal-Hirschman Index (HHI) for the investors in the member banks. ***, **, and * correspond to statistical significance at the 1%, 5%, and 10% level, respectively.

Observations	4854		6786			

The table reports the differences between facilities with high common ownership and facilities with low common ownership for the main variables of our sample. All variables are time demeaned. A facility is defined as high common ownership if the average level of profit weight between the lead bank(s) and the syndicate members falls in the upper quintile of the common ownership distribution. All variables are defined in Table A2. ***, **, and * correspond to statistical significance at the 1%, 5%, and 10% level, respectively.

The table reports the OLS regression parameter estimates and t-statistics of Equation (17). The dependent variable is the all-in-drawn loan spread, expressed in basis points. The covariate of interest is a measure of common ownership between the lead and member banks in the same syndicate. The model also control for facility-loan, lender, and borrower characteristics. Standard errors are clustered by lead bank. All variables are defined in Table A2. ***, **, and * correspond to statistical significance at the 1%, 5%, and 10% level, respectively.

Adjusted R-squared	0.441	0.443	0.363	0.369

The table reports the OLS regression parameter estimates and t-statistics of Equation (19). The dependent variable is the standard deviation of prices among facilities within the same loan (1)-(2) and same borrower-year (3)-(4). Common ownership is defined as the average profit weight between the lead arranger(s) and other syndicate members within the same loan (1)-(2) and same borrower-year (3)-(4). The model also controls for facility-loan, lender, and borrower characteristics. Standard errors are clustered by lead bank. All variables are defined in Table A2. ***, **, and * correspond to statistical significance at the 1%, 5%, and 10% level, respectively.

Table VIII: **Facility Loan Spread - Falsification Test**

The table reports the OLS regression parameter estimates and t-statistics of Equation (17) in Column (1) and (2) and Equation (18) in Column (3) and (4). The dependent variable is facility loan spread (Column 1 and 2) and the percentage of loan retained by the lead bank (Column 3 and 4). In Panel (a), the covariate of interest is a measure of common ownership member-lead. In Panel(b), the covariate of interest is a measure of common ownership member-member. The model also control for facility-loan, lender, and borrower characteristics. Standard errors are clustered by lead bank. All variables are defined in Table A2. ***, **, and * correspond to statistical significance at the 1%, 5%, and 10% level, respectively.

The table reports the OLS regression parameter estimates and t-statistics of Equation (17). The dependent variable is the all-in-drawn loan spread, expressed in basis points. Common ownership is defined as the average profit weight between the lead arranger(s) and other syndicate members. Column (1) contains loans issued to unrated borrowers, namely public companies that did not have a credit rating from Standard & Poors at the time of loan issuance. Column (2) contains loans issued to rated borrowers. Column (3) report the effect of syndicate common ownership on facility spreads for new lending relations. Column (4) report the effect of syndicate common ownership on facility spreads for repeated lending relations. Standard errors are clustered by lead bank. All variables are defined in Table A2. ***, **, and * correspond to statistical significance at the 1%, 5%, and 10% level, respectively.

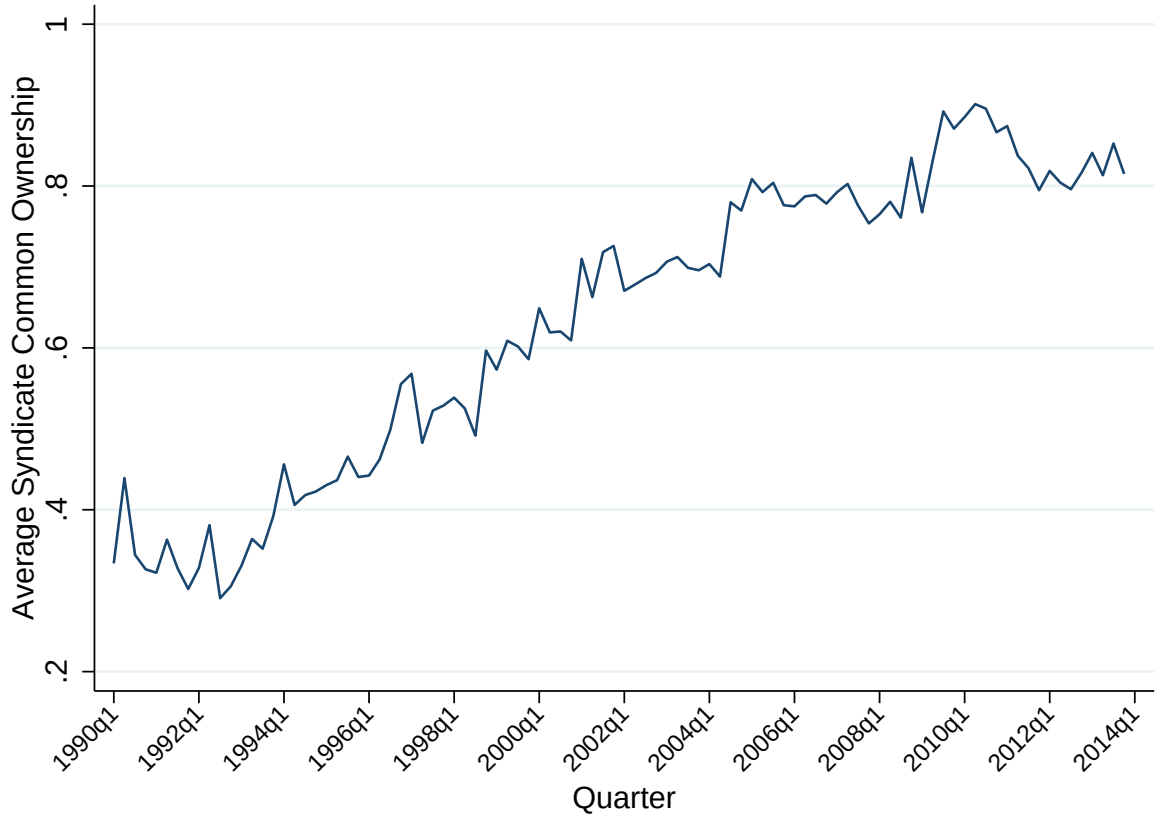
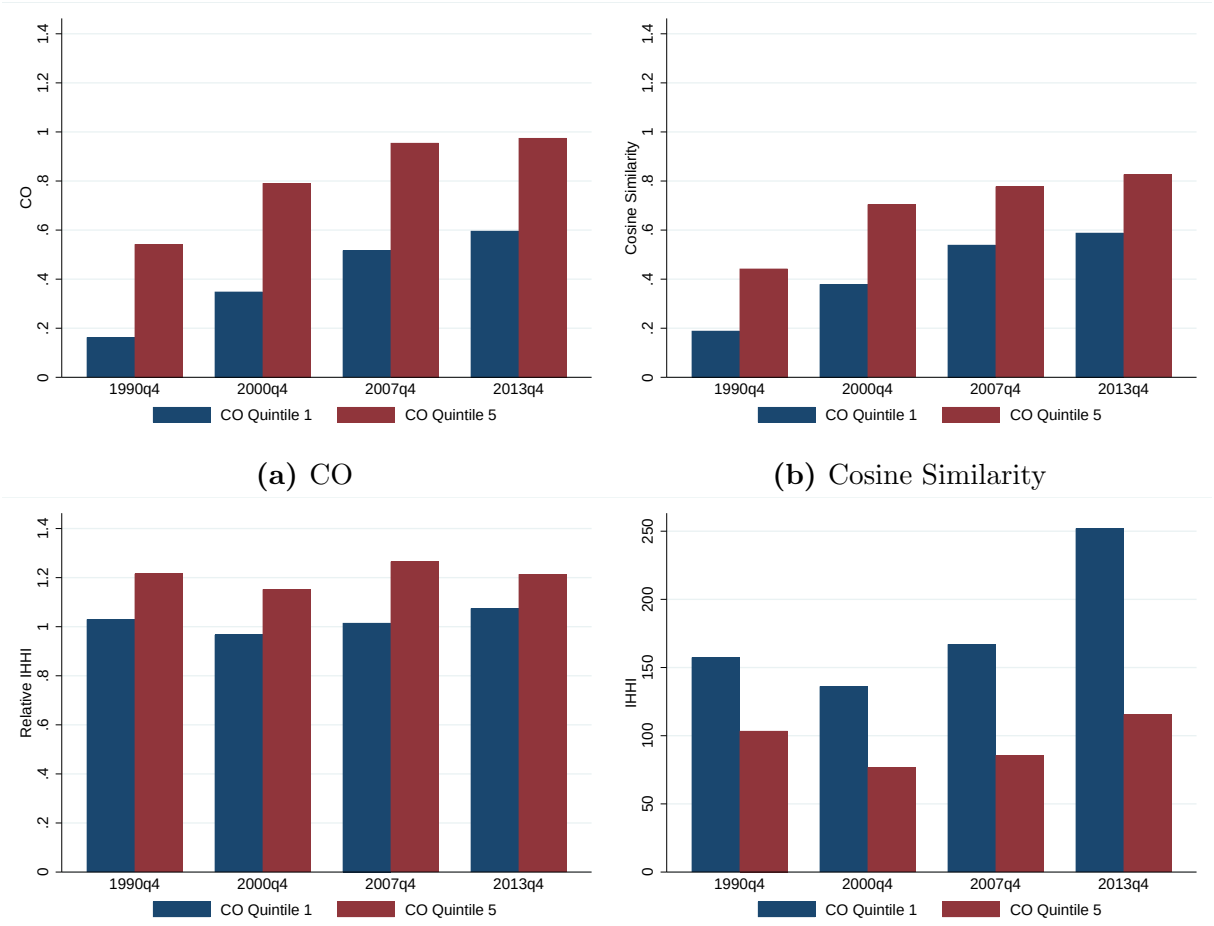
The table reports the the regression parameter estimates and t-statistics of a one-step OLS estimation of Equation (22) (Column 1) and a two-step estimation of Equation (21) and Equation (22) accounting for sample selection (Column 2 and 3). The dependent variable is the all-in-drawn loan spread, expressed in basis points. The covariate of interest is a measure of common ownership between the lead and member banks in the same syndicate. The model also control for facility-loan, syndicate member bank, and borrower characteristics. Standard errors are clustered by member bank. All variables are defined in Table A2. ***, **, and * correspond to statistical significance at the 1%, 5%, and 10% level, respectively.

Figure 1: **Average Syndicate Common Ownership Over Time**



This figure reports the average common ownership among banks in the same syndicate between 1990 and 2013 at a quarterly frequency. Common Ownership is defined as the average the profit weights between the syndicate lead-arranger(s) and the syndicate members.

Figure 2: **CO Decomposition**



(a) CO **(b)** Cosine Similarity

(c) Relative IHHI **(d)** Lead IHHI

The figure reports the average values of syndicate common ownership (a) and its decomposition (b) and (c) for the highest and lowest quintile of the common ownership distribution over time. Syndicate common ownership (CO) is defined in Equation 14 and the decomposition in Equation 15. Panel (d) reports the average shareholders' concentration of lead banks (Lead IHHI) for the highest and lowest quintile of the common ownership distribution over time.

This table reports the five largest shareholders of the three largest lead arrangers in the U.S. syndicated loan market. Ownership data comes from the Thomson Reuters s34 database.

Table A2: **Variable Definition**

Variable	Description
	Loan Variables
All-in-Drawn Spread	Facility all-in-drawn spread over the LIBOR rate
Mean Syndicate Profit Weight	Average profit weight between syndicate lead arranger and syndicate members
CO Bank-Firm	Average profit weight between borrower and syndicate banks
Facility Amount $M	Facility amount in 100 billion dollars
Log Maturity	Natural logarithm of the maturity of the facility in months
Secured Loan	Dummy variable equal to 1 if the facility is secured
Refinancing	Dummy variable equal to 1 if the purpose of the facility is refinancing
Log Number of Members	Natural logarithm of the number of syndicate members
Guarantor	Dummy variable equal to 1 if the facility has a guarantor
Relationship Score	$\frac{\frac{1}{N}\times\sum_j^N \text{Number of facilities between lead}_i \text{ and participant}_j \text{ in the past 3 years}}{\text{Number of facilities arranged by lead}_i \text{ in the past 3 years}}$
New Lending Relation	Dummy equal to 1 if the borrower has not received a loan from the lead arranger(s) in the syndicate before
LIBOR 3M	LIBOR 3-months rate at the time of the loan origination
Non-Bank Syndicate Member	Dummy variable equal to 1 if the facility has a non-bank lender in the syndicate
Volatility	SD of the borrower's stock return over the 12 months period before loan issuance
Credit Line	Dummy variable equal to 1 if the facility is a credit line
Term Loan A	Dummy variable equal to 1 if the facility is a term loan A
Term Loan B	Dummy variable equal to 1 if the facility is a term loan B or higher (C,D,...,H)
	Borrower Variables
Size	natural logarithm of the borrower's total assets
ROA	EBIT over total assets
Book Leverage	Debt over total assets
Tangibilities	PP&T over total assets PP&T over total assets
High Yield	Dummy variable equal to 1 if the borrower has a high-yield rating
Unrated Borrower	Dummy variable equal to 1 if the borrower is unrated
Tobin's Q	Market to book value
Log Int. Cov.	Log of 1 plus interest coverage truncated at 0
Liquidity Ratio	Cash over total asset
	Bank Variables
Bank Size	Natural logarithm of the bank's total assets
Bank Market Equity	Market value of equity capital over total assets
Bank Book Equity	Book value of equity capital over total assets
Bank Leverage	Bank debt over total assets
Bank ROA	EBIT over total assets

The table reports the OLS regression parameter estimates and t-statistics of Equation (17). The dependent variable is the all-in-drawn loan spread, expressed in basis points. Common ownership is defined as the sum of the minimum commonly held shares by investors between the lead arranger(s) and other syndicate members. Standard errors are clustered by lead bank. All variables are defined in Table A2. ***, **, and * correspond to statistical significance at the 1%, 5%, and 10% level, respectively.

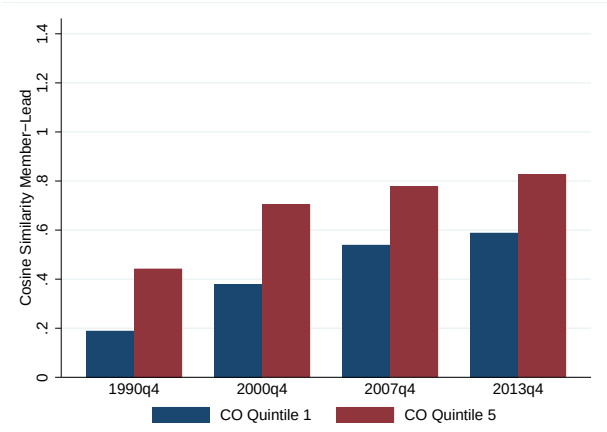
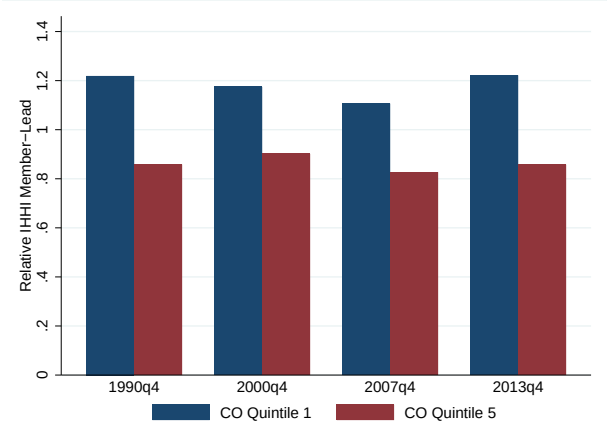
The table reports the OLS regression parameter estimates and t-statistics of Equation (17). The dependent variable is the all-in-drawn loan spread, expressed in basis points. Common ownership is defined as the average profit weight between the lead arranger(s) and other syndicate members. Standard errors are clustered by lead bank. All variables are defined in Table A2. ***, **, and * correspond to statistical significance at the 1%, 5%, and 10% level, respectively.

Figure 3: **CO Member-Lead Decomposition**



(a) Cosine Similarity



(b) Relative IHHI

The figure reports the decomposition of the average values of syndicate common ownership (Member-Lead) for the highest and lowest quintile of the common ownership (Lead-Member) distribution over time. Syndicate common ownership (CO) is defined in Equation 14 and the decoposition in Equation 15.
